**Abstract.** The diversity in appearance of diseased lung tissue makes automatic segmentation of lungs from CT with severe pathologies challenging. To overcome this challenge, we rely on contextual constraints from neighboring anatomies to detect and segment lung tissue across a variety of pathologies. We propose an algorithm that combines statistical learning with these anatomical constraints to seek a segmentation of the lung consistent with adjacent structures, such as the heart, liver, spleen, and ribs. We demonstrate that our algorithm reduces the number of failed detections and increases the accuracy of the segmentation on unseen test cases with severe pathologies.

**Keywords:** Pathological CT lung, lung detection and segmentation, anatomical constraints

## 1 Introduction

Healthy lung tissue is easily distinguishable from surrounding soft tissue in CT images due to its high air content. In contrast, pathologies like tumors, interstitial lung diseases (ILD), and plural effusion <sup>1</sup>, may dramatically alter both the appearance and texture of the lung and its surroundings (see Fig. 1). Due to this variability, automatic methods for segmenting healthy lung that rely on appearance alone, such as region growing or registration, are inappropriate for segmenting lungs from CT with severe pathologies [7].

In order to account for specific pathologies, such as ILD, some existing methods focus on utilizing texture cues [4, 11], or for tumors, robust statistical shape models can be used [9]. In order to robustly segment diseased lung parenchyma, other researchers have identified the need to use other nearby anatomical context. For example, the curvature of nearby ribs [6] or the distance to spine [2] can be used in addition to appearance information, or stable landmarks that take into account neighboring ribs can be used to better align a statistical shape model on the lung [8].

---

<sup>1</sup> Pleural effusion is an accumulation of pleural fluid between the parietal and visceral pleura, and thus part of the pleural cavity, but not of the actual lung. It is a common cause for decreased lung function and only affects the lungs directly. For this reason, we include both the lung and the pleural cavity in our segmentation.

**Fig. 1.** Examples of pathological lungs. In (a), the boundary between low/high intensity gives rise to a lung-like shape (red), making it hard to rely solely on a shape prior to segment pathologies.

**Fig. 2.** The proposed pathological lung segmentation pipeline.

However, none of these methods utilize all available anatomical context surrounding the lung regions. We propose a learning-based algorithm capable of segmenting lung from CT scans with several pathologies. From the outset, our algorithm is designed to be robust against pathologies, and relies on context external to the lung for each phase of the pipeline, including detection, coarse segmentation, and fine-scale refinement. For the segmentation, we take into account region-specific anatomical constraints using derived information such as distance to ribs or adjacent organs, such as liver and heart.

## 2 Methods

The lung is bounded by the ribs on the outside surface, the heart on the mediastinum side, and, e.g., the right lung is bounded by the liver on the bottom. In order to use these adjacent structures, our algorithm starts by automatically detecting them (e.g., lung, heart, liver & spleen §2.1) and rib segments (§2.2) using statistical classifiers. The lung mesh is then deformed using appearance cues and neighboring structures as geometric constraints (§2.3). A final detailed refinement balances the need for a fine-scale geometry while maintaining proximity to adjacent structures and ensuring no overlap between segmentations (§2.5). This final refinement maintains the integrity of the segmentation in the presence of pathologies by constraining the refined solution to lie close to the detected solution. The algorithm components and data flow are outlined in Fig. 2.

### 2.1 Organ detection

A central assertion in our approach is that we can apply region-specific geometric constraints to the segmentation. In order to apply such constraints, we need our

**Fig. 3.** Examples of rib lines (left), the 3D region parts for the right lung (middle), and region specific geometric constraints (right). The lung surface is divided into three partitions: the rib region (blue), the heart/mediastinum region (red) and the bottom region (green). Each region of the surface uses neighboring anatomy as constraints.

detected surfaces to be in correspondence with a template surface. To this end, we initialize our organ segmentation through the use of a statistical shape model that has been learned from training data.

Let  $\mathcal{C} = (\mathcal{V}, \mathcal{T})$  be a mesh with vertices  $\mathcal{V} = \{\mathbf{v}_i = (x_i, y_i, z_i)\}_{i=1}^n$  and triangles  $\mathcal{T}$ . We model shape variation with a point-distribution model [1] using a low-dimensional set of  $M$  shape modes,  $\mathbf{U}_j = \{\mathbf{u}_{ij}\}_{i=1}^n$ , and a mean vector  $\bar{\mathbf{v}}_i$ :  $\mathbf{v}_i = \bar{\mathbf{v}}_i + \sum_{j=1}^M \lambda_j \mathbf{u}_{ij}$ , where  $\{\lambda_j\}_{j=1}^M$  is a shape coefficient vector defining the shape. Given a transformation,  $T(\mathbf{v}; \theta)$  parameterized by  $\theta$ , e.g., a similarity transform, the initial organ detection seeks the most probable configuration given the input image,  $I$ :

$$\mathcal{C}^0 = \operatorname{argmax}_{\mathcal{C}} P(\mathcal{C}|I, \{\bar{\mathbf{v}}_i\}, \{\mathbf{u}_{ij}\}) = \operatorname{argmax}_{\mathcal{C}} P(\theta, \{\lambda_j\}_{j=1}^M | I, \{\bar{\mathbf{v}}_i\}, \{\mathbf{u}_{ij}\}). \quad (1)$$

This problem is solved with the discriminative method marginal space learning [12], and it is used to reliably estimate an initial object segmentation of the lungs,  $\mathcal{C}_{\text{lung}}^0$  &  $\mathcal{C}_{\text{rlung}}^0$ , heart,  $\mathcal{C}_{\text{heart}}^0$ , spleen,  $\mathcal{C}_{\text{spleen}}^0$ , and liver,  $\mathcal{C}_{\text{liver}}^0$ , (e.g., [5]).

For the lungs, to avoid failed detection on large effusions with dramatically different appearance, we first estimate the shape on a contrast adjusted input image,  $I_{win} = \max(0, \min(1, (I - 80)/496))$ , where  $I$  is in Hounsfield unit (HU).

## 2.2 Rib Points Extraction

In order to extract points on the ribs to be used as constraints, discriminative classifiers are used to identify likely rib points. These likely rib points are then grouped into short segments, and unlikely segments are culled (Figure 3).

First, a per-voxel rib probability map,  $I_{rib}(\mathbf{x})$ , is obtained from a two-level cascade of discriminative classifiers,

$$I_{rib}(\mathbf{x}) = P_{2\text{mm}}^{\text{rib}}(+1|I_{2\text{mm}}, \mathbf{x}) \pi[P_{2\text{mm}}^{\text{rib}}(+1|I_{2\text{mm}}, \mathbf{x}) > \tau_2] \pi[P_{4\text{mm}}^{\text{rib}}(+1|I_{4\text{mm}}, \mathbf{x}) > \tau_1] \quad (2)$$

where  $\pi[\cdot]$  is an indication function,  $P^{\text{rib}}$  are rib point classifiers trained using Haar features [10],  $\tau_1$  is a threshold used to limit computation in the 2nd level (2mm) to highly likely voxels, and  $\tau_2$ <sup>2</sup> is used to further threshold the 2mm

<sup>2</sup> In practice, we tune  $\tau_1$  and  $\tau_2$  through the ROC curve and the final performance is insensitive to small changes in these parameters.

**Fig. 4.** Two points on the current mesh surface.  $\mathbf{v}_i$  is a healthy point, so the appearance term is reliable, and the geometric term has little effect as indicated by the response curves as a function of depth. On the other hand,  $\mathbf{v}_j$  is a pathological point and the appearance term is misleading. The product of appearance and geometry gives the correct displacement.

classifier response.  $I_{4mm}$  and  $I_{2mm}$  are volumes that have been isotropically resampled to the corresponding resolution.

From the rib probability map  $I_{rib}$ , connected components of the thresholded mask are obtained. Each segment is grown to a maximum of size of  $s_{max} = 9000\text{mm}^3$ . Components less than  $s_{min} = 2000\text{mm}^3$  are pruned. The remaining segments should be like bent cylinders. To prune candidate segments that are not like bent cylinders, a final test on the sizes of the segment along its principle directions is performed. Let  $\alpha_1 > \alpha_2 > \alpha_3$  denote the sizes of the segment in its three principle directions. Remaining segments are pruned if  $\frac{\alpha_1}{\alpha_2} < 2.5$  or  $\frac{\alpha_2}{\alpha_3} > 3$ .

Finally, the center points of each segment are extracted by traversing along its principal direction and intersecting a fixed number of planes with the segment.

### 2.3 Pathological Lung Surface Refinement

The key component of the pathological boundary detector is to combine image appearance cues with spatially dependent anatomical constraints that come from the ribs and organs detected using methods in the previous sections. The mesh initialization from §2.1 is already in correspondence with a known atlas. Also, the indices,  $\mathcal{I} = \{1 \leq i \leq n\}$  of the mean mesh vertices are partitioned into 3 subsets:  $\mathcal{I} = \mathcal{I}_{ribs} \cup \mathcal{I}_{heart} \cup \mathcal{I}_{bottom}$ , each subset corresponding to one anatomical region. During boundary refinement, each vertex independently is deformed to  $\mathbf{v}_i \leftarrow \mathbf{v}_i + t_i \mathbf{n}$ , where

$$t_i = \operatorname{argmax}_{t \in [t_{min}, t_{max}]} P_i(t|I), \quad (3)$$

with the search being locally constrained within a range  $[t_{min}, t_{max}]$ . The resulting displaced mesh is regularized by projection onto the shape subspace, and the process is repeated for a few iterations.

The per-vertex score in (3) is computed as a combination of appearance,  $f_i^a(t)$ , and structural cues,  $f_i^g(t)$ ,  $P_i(t|I) = f_i^a(t)f_i^g(t)$ . We assume  $f_i^a(t)$  is the best model to use assuming no pathology. However, the opposite is true for pathological surfaces, where appearance cues are misleading, and we rely on  $f_i^g(t)$ . Figure 4 illustrates how the geometric term helps in the case of a pathology.

**Fig. 5.** If lung regions adjacent to the rib surface are too far from the ribs, the input is identified as pathological. For the bottom region, the pathological pipeline will be activated if the surface is not close enough to the adjacent organ (e.g., liver or spleen).

Unlike previous methods that model the appearance term with an image gradient (e.g., [9]), or region-based term, we instead use a discriminative model for the appearance in the form of a classifier that is learned from training data [5]:

$$f_i^a(t) = P(+1|\mathbf{v}_i + t\mathbf{n}_i, I). \quad (4)$$

The classifier,  $P(+1|\mathbf{v}_i + t\mathbf{n}_i, I)$ , measures the probability that the displaced point  $\mathbf{v}_i + t\mathbf{n}_i$  belongs to the surface of the lung. To model this posterior, we use a probabilistic boosting tree with steerable features [12].

The anatomical term,  $f_i^g(t)$ , penalizes the surface from being far away from the adjacent structure using a Gaussian kernel mixed with a uniform prior:

$$f_i^g(t) = \exp\left(-\frac{(t - (\mathbf{y}_{\text{struct}}(\mathbf{v}_i) - \mathbf{v}_i)^T \mathbf{n}_i - \tau_i)^2}{2\sigma_i^2}\right) + \frac{\alpha}{t_{\text{max}} - t_{\text{min}}}, \quad (5)$$

where  $\mathbf{y}_{\text{struct}}(\mathbf{v})$  is the closest point on the adjacent relevant structure from the source point  $\mathbf{v}$ . The per-vertex  $\tau_i$  parameter allows for a spatially varying offset between the adjacent structure and the lung surface being segmented. These spatially varying parameters account for errors in mesh correspondence and unreliability of geometric constraints, e.g., on regions close to the spine. Adding the uniform prior reduces the influence of the geometric in the case that  $\mathbf{y}_{\text{struct}}(\mathbf{v})$  is far away from  $\mathbf{v}_i$ .

We estimate the spatial varying  $\{\tau_i\}$  and  $\{\sigma_i\}$  from a given set of  $K$  training instances. We first compute for each vertex  $i$  an estimate of  $\tau_i$  as the average distance to the neighboring structure from that point:  $\bar{\tau}_i = \frac{1}{K} \sum_k \tau_{i,k}$ , with  $\tau_{i,k}$  being the distance estimated for training sample  $k$ . The standard deviation can be used as an estimate for  $\sigma_i$ . To ensure these values vary smoothly over the surface, we perform a weighted smoothing operation over the surface of the mesh,  $\tau_i = (\bar{\tau}_i + \text{mean}_{j \in N(i)}(\bar{\tau}_j))/2$ , where  $N(i)$  are neighbors of vertex  $i$ .

## 2.4 Identifying Pathological Lungs

To make our pipeline capable of also efficiently handling healthy lung cases, we only apply the pathological boundary processing if the initialization from the basic pipeline is determined to be pathological. Determining if a case is healthy or pathological also uses anatomical constraints. A lung is determined

as pathological when either the anatomical constraints between the lung/rib surface and lung/bottom organ surface are not satisfied. (Fig. 5).

For the lung/rib surface, first, we sample the rib probability image above the surface of the lung attached to the rib and take the maximum value of  $I_{rib}$  at values of 2mm, 4mm, and 6mm above the lung surface. We then produce a binary function on the lung surface for regions of the lung surface that are confidently close to a rib as  $\chi(\mathbf{v}) = (\max_{t=2,4,6} I_{rib}(\mathbf{v} + \mathbf{n}t)) > 0.67$ . If any part of the rib-adjacent lung surface is more than 25mm from a point with  $\chi(\mathbf{v}) = 1$ , then we declare that the lung is a pathology. Figure 5 illustrates the regions of the surface near a rib, as well as the red region farther than 25mm.

To identify cases where the bottom region is pathological, the vertices on the bottom region that are closely coupled to the bottom organ are identified as  $A = \{\mathbf{v}_i : i \in \mathcal{I}_{bottom}, \sigma_i \leq 5\}$ . If too many vertices in  $A$  (e.g., 15%) are far from the bottom organ (say beyond  $3\sigma_i$ ), we perform the pathological processing.

## 2.5 Final Refinement

Although the explicit mesh-based representation above allowed us to easily define region-specific anatomical constraints that were necessary to segment pathological lungs, the mesh-based surface representation is inadequate in obtaining voxel-level fine-scale detail. In order to obtain a more precise segmentation, we convert the initialized mesh surfaces into an implicit formulation and perform a fine-scale refinement using level sets [3]. The level set representation allows us to integrate appearance-based data terms with anatomical constraints (such as non-overlapping constraints) between neighboring organs. See [3] for details.

## 3 Experiments

Our lung detectors and related parameters have been trained on a total of 185 right lung and 196 left lung cases. The MSL classifiers were trained on 3mm isotropic volumes. Using the percentage of ground truth lung volume with values greater than 512 HU as an indicator of the severity of the pathology, the majority of our training examples are from healthy lungs: only 7 (resp. 2) left (resp. right) lung cases had between 25%-50% unhealthy tissue.

We test our pipeline on a set of CT images containing 17 left and 33 right lung pathologies having an average dimension of  $465 \times 448 \times 328$  and spacing of  $1.11 \times 1.11 \times 2.61$ mm. Our cases have 12 left lungs with greater than 25% unhealthy tissue, 5 of which are greater than 50%. There are 21 right lung cases with greater than 25% unhealthy tissue and 10 cases with greater than 50% unhealthy tissue. The average run time for our test cases is 64s, including processing time for lung, liver, heart, and spleen, and ribs. All training and test data sets are manually annotated by experts.

The basic detection pipeline that relies on the input image only to detect the bounding box fails on 3/17 and 5/33 cases for left and right lung respectively (i.e., bounding box fails to return a box with high enough confidence). Table 1 illustrates statistics on mean surface-to-surface distance error (in mm) and volumetric statistics for the unseen test set. The error was only computed on the

**Fig. 6.** Lung segmentation without (top) and with anatomical constraints (bottom) using the heart (red) and liver (blue). Errors decrease from 8.55mm to 4.49mm, 22.26mm to 6.16mm, 4.7mm to 3.3mm, and 3.2mm to 2.57mm.

**Table 1.** Average surface-to-surface error (Mean, median, and 80% highest error in mm) & volumetric stats (Dice Coeff and Relative Volume Difference) on unseen cases.

	Mean(STD)	Median	80%	Dice Coeff	Rel.Vol.	Fail
L.Lung Basic	4.76(2.47)	4.23	7.18	0.84	-0.14	3
L.Lung Path.	3.44(0.96)	3.84	4.25	0.89	-0.06	0
L.Lung LevSet	2.49(1.14)	2.19	3.69	0.91	0.01	0
R.Lung Basic	5.72(3.96)	4.02	8.25	0.85	-0.19	5
R.Lung Path.	3.64(1.21)	3.36	4.31	0.91	-0.06	0
R.Lung LevSet	2.23(0.97)	2.01	2.69	0.94	0.06	0

non-failure cases. In the table, the mean and median errors decrease after using the pathological pipeline. But as pathologies may only occupy a small region of the surface, the error measure between the basic detection and pathological detection may only decrease slightly.

In the case of large tumors and effusions, the use of the anatomical constraints is essential to providing a geometric consistent lung segmentation. This is better illustrated with examples (Fig. 6). The geometric constraints give a segmentation that hugs the rib boundary regardless of appearance. The final refinement causes a decrease in surface error on all regions (including healthy regions), further boosting the performance. Fig. 7 shows the final level set refinement on several challenging cases.

## 4 Conclusions

The original image is affected by large changes due to pathological lung appearance. Our experiments have shown that structural constraints are necessary to accurately segment pathological lungs, when combined with statistical learning. Future improvements include more accurate rib segmentation, better correspondence in our shape models, or including other anatomical constraints, for example, from the aorta.
